- Elastic and inelastic proton scattering on ^{12}C was measured at 300 MeV with specific attention on the structure of the $E_x=7654$ keV Hoyle state. The 300 MeV proton beam, from the Osaka University Research Center for Nuclear Physics cyclotron, impinged on ^{nat}C (30 mg/cm^2) or polyethylene (4.6 mg/cm^2) targets and the angular distributions ($\theta=2.7^\circ$ to 40°) were measured in the “Grand Raiden” spectrometer. Optical potential parameters for the elastic distributions were obtained in ECIS95 analysis, while the inelastic data were analyzed via three DWBA approaches (1) macroscopic collective model (2) microscopic α -cluster model (3) microscopic α -cluster condensation model.

The width of $^{12}\text{C}^*(9641)$ was measured.

A 66 MeV proton beam impinged on a 1 mg/cm^2 ($\Delta E \approx 9 \text{ keV}$) thick ^{nat}C target at the iThemba LABS in South Africa. Scattered protons were momentum analyzed at $\theta_{lab}=10^\circ$, 16° and 28° using the K600 spectrometer. Target energy loss effects were minimized by rotating the target angle to $\theta=0^\circ$, 5° and 14° for the different spectrometer settings, respectively; a systematic uncertainty of 2 keV is associated with energy loss differences for the interaction location in the target. The overall system resolution of 23 keV FWHM is deduced from analysis of the $^{12}\text{C}^*(7654)$ state peak. The $^{12}\text{C}^*(9641)$ peak was first analyzed by fitting a resolution convoluted Voigt lineshape resulting in $\Gamma=40.4 \text{ keV}$. However, the decay mechanism, $L=3$ via $^8\text{Be}_{g.s.}$, distorts the lineshape and a more complex R-matrix formalism was selected for the preferred fit. In this case $\Gamma=48 \text{ keV}$ is deduced. This width is 30% of the Wigner limit and implies a significant α -particle content for the state.
